Postpolio syndrome (PPS) occurs in a significant proportion of polio survivors years after recovering from the original illness[1,2]. Anaesthetists need to be aware of the syndrome as polio survivors are relatively numerous (40,000 cases of paralytic polio in Australia from the 1950s to the 1960s), they are of an age where they will be increasingly presenting for elective and emergency procedures and the syndrome has important implications for the planning and delivery of anaesthesia[3]. Poliomyelitis results from an entroviral infection that damages anterior horn cells in the spinal cord and results in flaccid paralysis with slow improvement over months or years. It may also be associated with encephalitic changes affecting the brainstem nuclei particularly in the medulla, the cerebellum and the reticular formation and as a result may cause bulbar and autonomic dysfunction as well as alterations in mental state[4].

PPS typically occurs 20 to 40 years after the acute poliomyelitis episode[5]. Although the exact mechanisms of the PPS are debated[6–8], neurological dysfunction worsens or recurs in areas affected during the original illness.

This is most commonly manifested as progressive muscle weakness, fatigue or pain in the muscles and joints. However, respiratory failure, sleep disordered breathing and bulbar dysfunction with dysphonia, dysphagia or poor cough may also occur[9]. Cold intolerance is also common[10]. Preoperative assessment in PPS patients should define the nature of the initial poliomyelitis episode including areas affected, severity and current functional capacity. A history of polio requiring mechanical ventilation, with bulbar dysfunction and as a result may cause bulbar and autonomic dysfunction as well as alterations in mental state[4].

Patients with PPS are generally considered to have increased sensitivity to opiates, muscle relaxants, sedative and anaesthetic drugs leading to recommendations to start low and titrate carefully[11–13]. This is probably multifactorial reflecting changes in the reticular activating system, muscle atrophy and weakness due to denervation and reduced volume of distribution due to muscle loss.

In relation to muscle relaxants, PPS patients are said to be twice as sensitive to non-depolarising muscle relaxants with a recommendation to use a short-acting agent, starting with half the usual dose and carefully titrating therapy with neuromuscular monitoring against a baseline twitch response[14].

Avoidance of suxamethonium where possible is recommended as it may result in greater post-operative muscle pain and concerns remain regarding the risk of hyperkalaemia although evidence is lacking[15–16]. Regional anaesthesia has been successfully used[17–18] and where feasible may result in fewer complications although delayed muscle recovery may occur[19]. Other intraoperative factors to consider are patient positioning which may be difficult due to contractures, a high fracture risk from associated osteoporosis and increased risk of respiratory failure, sleep disordered breathing and bulbar dysfunction with dysphonia, dysphagia or poor cough may also occur[9]. Cold intolerance is also common[10].

Awake positioning prior to surgery may minimise these risks. Attention to warming intraoperatively is important to prevent hypothermia and distressing post-operative shivering due to abnormal thermoregulation[20–21].

Postoperative respiratory failure related to oversedation and weakness has been reported[22] and consideration should be given to increased post-operative monitoring in an HDU environment[23–24]. Slow emergence and respiratory concerns will preclude day surgery for the majority[25]. Pain management may be difficult both due the presence of chronic pain and concerns relating increased sensitivity to the sedative and respiratory depressant effects of analgesics[26–27].

Postpolio syndrome patients present a number of potential problems for the anaesthetist. However for those who are aware of the syndrome, careful assessment and planning should minimise the risk of perioperative complications and provide optimal patient outcomes.
